Key Words

Breast cancer · Treatment decision · Depression

Summary

Background: Breast cancer is the most common cancer in women. Primary treatment is surgery, with breast conserving surgery (BCS) being widely used for early-stage disease. Due to changes in body image, depressive symptoms can occur after surgery. Here, we evaluate factors that affect patients' decision on surgery, and investigate differences in the level of depression after mastectomy or BCS in a population of Turkish patients. **Patients and Methods:** One hundred breast cancer patients who had undergone mastectomy or BCS and were followed up at our institution between 2007 and 2008 were included. Patients were questioned about their involvement in surgical decision-making. Depression was diagnosed according to the Diagnostic and Statistical Manual of Mental Disorders (DSM-III) criteria via a Structural Clinical Interview for DSM (SCID). Severity of depression was evaluated by using the Beck Depression Inventory (BDI). **Results:** Patients who were older than 50 years, had more than 1 child, a history of lactation, and a positive family history of breast cancer mostly preferred mastectomy. However, patients who sought a second opinion and further information on BCS preferred BCS ($p < 0.005$). There was no statistical correlation between marital status, first childbearing age, and educational status and the decision on surgery type ($p > 0.005$). Mastectomy patients were prone to depression, but this was not statistically significant ($p = 0.099$). **Conclusion:** Age, parenthood, lactation, and positive familial history, as well as thorough information about the type of surgery were important factors for the patients' decision. After breast cancer surgery, patients might experience depression affecting treatment and quality of life. Therefore, adequate information and communication are essential.

Brustkrebs · Therapieentscheidung · Depression

Zusammenfassung

Hintergrund: Brustkrebs ist die häufigste Krebserkrankung der Frau. Die primäre Therapie ist die chirurgische Behandlung, und im früheren Erkrankungsstadium kommt die brusterhaltende Operation (breast conserving surgery, BCS) häufig zum Einsatz. Auf Grund des veränderten Körperbildes kann es zum Auftreten depressiver Symptome nach der Operation kommen. In der vorliegenden Arbeit ermitteln wir Faktoren, die Brustkrebspatientinnen bei der Wahl der chirurgischen Behandlung beeinflussen. Desweiteren werden Unterschiede im Ausmaß der Depression nach Mastektomie bzw. BCS in einer türkischen Patientenpopulation untersucht. **Patienten und Methoden:** Einhundert Brustkrebspatientinnen, bei denen entweder eine Mastektomie oder BCS durchgeführt wurde, und die zwischen 2007 und 2008 an unserer Institution weiterverfolgt wurden, nahmen an der Studie teil. Die Patientinnen wurden zu ihrer Beteiligung an der Entscheidungsfindung bezüglich der Art der Operation befragt. Depression wurde basierend auf den DSM-III (Diagnostic and Statistical Manual of Mental Disorders)-Kriterien über ein SCID (Structural Clinical Interview for DSM) diagnostiziert. Das Ausmaß der Depression wurde mithilfe des BDI (Beck Depression Inventory) ermittelt. **Ergebnisse:** Patientinnen, die älter als 50 Jahre waren, mehr als ein Kind hatten, gestillt haben und eine positive Familienanamnese in Bezug auf Brustkrebs aufwiesen, bevorzugten in der Regel eine Mastektomie. Patientinnen, die jedoch eine zweite Meinung und nähere Informationen zu BCS eingeholt hatten, zogen eine BCS vor ($p < 0,005$). Es bestand keine statistische Korrelation zwischen Ehestand, Alter bei Geburt des ersten Kindes, Bildungsstand und der Entscheidung bezüglich der Operationsart ($p > 0,005$). Mastektomie-Patientinnen neigten zu Depressionen, aber dies war statistisch nicht signifikant ($p = 0,099$). **Schlussfolgerung:** Alter, Elternschaft, Stillen und positive Familienanamnese sowie ausführliche Informationen zum Operationstyp waren wichtige Faktoren bei der Entscheidungsfindung. Brustkrebspatientinnen können an postoperativer Depression leiden, die ihre Therapie und Lebensqualität beeinflusst. Adäquate Information und Kommunikation sind deshalb von großer Wichtigkeit.

Introduction

Breast cancer is the most commonly diagnosed malignancy in women [1]. Although mastectomy is the standard treatment for breast cancer, breast conserving surgery (BCS) plus radiotherapy is equivalent to mastectomy in terms of survival [1–3]. In 1991, the National Cancer Institute suggested BCS as the preferred surgical treatment for early-stage breast cancer [4]. It was assumed that BCS would largely replace mastectomy, but this has not occurred as currently over one third of early breast cancer patients are treated with mastectomy [2, 5, 6].

The treatment decision is based on tumor characteristics, the surgeon's experience, and the patient's preference [1, 5]. If treatment preferences of the patients can be well understood, more effective decision making may be established [1]. A number of studies have investigated the factors that affect patients in their choice of surgery [6–9]. These factors are age, tumor size, placement, socioeconomic factors, race, and marital status. In the literature, it was reported that age and education were important for BCS preference [1, 10]. Also, preference of the surgeon was a major factor influencing the patients' decision making [1, 5]. One hypothesis stated that inadequately informed patients chose mostly mastectomy [2]. Younger patients had greater concerns about body image and sexuality [5], so age may influence decision-making about breast cancer surgery.

Cancer diagnosis is described as one of the most stressful medical diagnoses a person can receive [11, 12]. The majority of cancer patients have some degree of depression, and 50% of this population meet the criteria for a psychiatric diagnosis [11, 13]. Many patients have psychiatric morbidities, especially anxiety and depressive disorder [14, 15]. The rate of diagnosis of depression ranges between 6 and 46% [11, 12, 14, 16, 17]. Psychological distress and anxiety were found to predict overall survival and quality of life in breast cancer patients [18]. Several studies have attempted to evaluate the psychological impact of different surgical treatments on patients with breast cancer [15, 19]. The psychiatric morbidity associated with mastectomy in the first year of treatment was also reported [19, 20]. Differences about psychosocial outcome between mastectomy and BCS were also previously reported [16, 21]. Although BCS is considered to be the least disfiguring treatment option, esthetic outcomes vary. The majority of women report breast asymmetry and disfigurement, and failure to adapt to loss of breast tissue. So anxiety and depression are seen after BCS as well as mastectomy [16, 21]. Treatment of depression in breast cancer patients improves quality of life and may increase survival [17]. With an early diagnosis and timely referral to a psychiatrist, patients could have a more comfortable life.

A number of screening instruments has been studied in the oncology setting to improve recognition of depression [22]. In psychiatric research, self-administered scales are frequently used in diagnosing and assessing the severity of depression

[13]. The Beck Depression Inventory (BDI) is a reliable and quick screening instrument and is used worldwide in psychiatric and non-psychiatric patients [13].

In this study, we aimed to detect any differences between mastectomy and BCS in relation to psychological morbidity in a population of Turkish breast cancer patients. At the same time, factors that affect patients' treatment choices between BCS and mastectomy, as well as the psychological impact of such a choice, were investigated.

Patients and Methods

One hundred women with breast cancer who underwent mastectomy or BCS and were followed up in the Department of Medical Oncology in the Dr. Lutfi Kırdar Research and Education Hospital between December 2007 and March 2008 participated in this study. Eligibility criteria for the study included: confirmed diagnosis of breast cancer, no previous cancer or untreated psychopathology, age between 30 and 80 years, having undergone mastectomy or BCS as breast cancer treatment. All patients were followed up at the outpatient clinic at regular intervals and evaluated retrospectively. Patient histories were taken; demographic factors like age, marital status, having had children, lactation, family history, and operation type were noted. All women provided oral and written informed consent, indicating their awareness of the investigational nature of the study. The demographics form was completed; thereafter patients were given a self-report questionnaire including 33 items relating to the effect of cancer on the patient's mood. In this questionnaire, 7, 14, and 12 items related to anxiety, denial, and depression, respectively. After the patients had answered the questions, responses were scored to detect psychological morbidities in these categories, and compared between the mastectomy and BCS group. Psychiatric symptoms were elicited using a Structural Clinical Interview for DSM (SCID), and classified according to the Diagnostic and Statistical Manual of Mental Disorders (DSM-III) criteria. SCID is the gold standard clinical interview for research diagnosis of depression according to DSM-III criteria [23]. BDI was used to evaluate the severity of symptoms of depression; it was self-administered and took 5–10 minutes. BDI is composed of 21 items and a quick screening instrument. It is used worldwide in both psychiatric and non-psychiatric patient populations. Beck et al. [13] recommended a score of 10 when screening for mild depression, 16 for mild to moderate depression, 20 for moderate to severe depression, and 30 for severe depression.

Statistical Analysis

Descriptive statistics were computed for all variables. To explore the relationship between patients' treatment decisions and demographic features, the chi-square test was used. To compare the depression, anxiety, and denial score between the mastectomy and BCS group, the Mann-Whitney U test was used. All statistic analyses were conducted using SPSS 13.0 (SPSS Inc., Chicago, IL, USA), and a p value less than 0.05 was considered as statistically significant.

Results

Table 1 details the characteristics of the patients. A total of 100 Turkish women with breast cancer were included, modified radical mastectomy was performed in 78 of them, while the others underwent BCS. Approximately 60% of the pa-

tients were younger than 50 years of age. Demographic factors that affect the patients' choice of surgery type for breast cancer were evaluated. The patients' age, number of children, lactation history, and second opinion from another surgeon about the surgery type were found to be related to the patients' preferences. Patients younger than 50 years of age were more likely to prefer BCS. The median age of patients who underwent mastectomy or BCS was 40.5 and 49.0 years, respectively. While above 80.0% of the patients who preferred BCS were younger than 50 years of age, of the patients who underwent mastectomy, 53.8% were younger than 50 years. So it could be said that older patients mostly preferred mastectomy rather than BCS, and this was statistically signifi-

cant ($p = 0.025$). In both groups, mastectomy or BCS, approximately 80.0% of patients were married. While in the mastectomy group 96% of patients had one or more children, in the BCS group, this figure was 77.0%. Patients with children wanted a mastectomy rather than BCS, and this was statistically significant ($p = 0.004$). Like having children, lactation history also had a direct effect on the patients' treatment decision. In our patients, 72.7% of patients in the BCS group and 94% of patients in the mastectomy group had a lactation history ($p = 0.007$). The 25% of patients who consulted another surgeon preoperatively, mostly preferred BCS ($p = 0.023$). Out of the 58 patients with a family history of breast cancer, 49 wanted a mastectomy, although there was no statistically significant correlation ($p = 0.088$). Factors such as marital status, first childbearing age, and educational status were similar in both groups and did not appear to play a critical role in the decision making process. There was no statistically significant correlation ($p > 0.005$). In addition, we could not find any relation between tumor histopathological type and decision making.

After surgery, 69 and 18 women who had undergone mastectomy and BCS, respectively, had mild depressive symptoms according to BDI, which were not serious enough to warrant psychiatric help. Although there was no significant relation between mastectomy or BCS and depression, patients with mastectomy had more evident depressive symptoms ($p = 0.099$). Also, there was no difference between the anxiety and denial score between the mastectomy and BCS group (table 2). Overall, in this Turkish population, many of the women who had undergone mastectomy seemed to have a poorer quality of emotional life although this was not significant.

Discussion

Breast cancer is the most commonly diagnosed cancer in women, and as a component of treatment nearly all will face surgery – BCS or mastectomy [3]. In early-stage breast cancer, BCS is equivalent to mastectomy in terms of survival [1, 2, 5]. In the absence of survival and quality of life differences, the treatment decision can be made according to the patient's preferences [1].

Table 1. Patient characteristics

Characteristics	BCS (n = 22)	MRM (n = 78)	p
Age, median (range), years	40 (30–55)	49 (34–70)	
	Patients, n (%)		
Age			0.025
>50 years	4 (18.2)	36 (46.2)	
<50 years	18 (81.8)	42 (53.8)	
Marital status			1.00
Married	17 (77.3)	59 (75.6)	
Single	5 (22.7)	19 (24.4)	
Childbirth			0.004
Present	17 (77.3)	74 (94.9)	
Absent	5 (22.7)	4 (5.1)	
Lactation			0.007
Present	16 (72.7)	74 (94.9)	
Absent	6 (27.3)	4 (5.1)	
Family history			0.088
Present	9 (40.9)	49 (62.8)	
Absent	13 (59.1)	29 (37.2)	
Education			0.213
High	10 (45.5)	24 (30.8)	
Low	12 (54.5)	54 (69.2)	
Second opinion			0.023
Present	10 (45.4)	15 (19.2)	
Absent	22 (54.6)	63 (80.8)	

MRM = Modified radical mastectomy; BCS = breast conservative surgery.

Table 2. Depression anxiety score between MRM and BCS

	BCS, median (range)	MRM, median (range)	p
BDI score	11 (0–29)	8 (0–42)	0.099
SCID			
Anxiety score (7 points)	2 (0–6)	2 (0–7)	0.293
Depression score (12 points)	5.5 (0–11)	5 (0–11)	0.977
Deny score (14 points)	8 (2–13)	9 (2–16)	0.356

MRM = Modified radical mastectomy; BCS = breast conservative surgery; BDI = Beck Depression Inventory; SCID = Structured Clinical Interview for.

Studies have shown that as well as clinical factors like tumor size or nodal involvement nonclinical factors like age, socioeconomic status, and race were also important variables in predicting the choice of mastectomy or BCS; younger and married patients and those with higher stages of cancer were shown to be more likely to choose mastectomy [2]. Breast cancer is mostly seen with increasing age [24]. In our study, 22 patients had undergone BCS, and the other 78 had undergone mastectomy. We detected a relationship between age and choice of surgery; in the mastectomy group more than 46% were older than 50 years while in the BCS group only 18.2% were above 50 years. Although tumor size was not evaluated in this study, age was an important factor in deciding the type of surgery. Bleicher et al. [9] reported that there was no significant relation between age and surgery type, and two significant predictors of treatment with mastectomy and BCS were degree of patient involvement in decision making and tumor size. Martin et al. [2] also showed that patients with small tumors tended to choose BCS regardless of other factors but patients with large tumors aged over 60 years or younger than 60 years with nodal involvement tended to choose mastectomy. Chagpar et al. [10] found that patients mostly underwent BCS rather than mastectomy; out of 2,762 patients 67.6% underwent BCS, and the authors agreed that older patients and those with larger tumors and lobular carcinoma type preferred mastectomy due to being less concerned with cosmetic outcome. We did not report tumor type, size, or histopathological properties. Although in previous studies, a higher education level was associated with choosing BCS due to a better understanding of the information regarding recurrence [1], in our study education status was not correlated with the patients' decision on surgery and was similar in both groups. Some patients may inaccurately think that their chance of surviving cancer improves when choosing mastectomy. In the Turkish population, mastectomy is still preferred to BCS. Besides age, patients with more than 1 child and with a lactation history widely preferred mastectomy. Also, patients with a positive family history of breast cancer chose mastectomy more than BCS. This might be influenced by the fact that in our population, women accept that the breast's purpose is lactation rather than being concerned with cosmetic appearance. Patients might think that removing all breast tissue avoids recurrence and disease progression. Therefore, they prefer mastectomy in spite of poor cosmetic outcome.

Psychological distress, anxiety, and depression were found to be common in the range of 1.5–46% among breast cancer patients, and psychological factors were found to predict quality of life and overall survival in breast cancer [14, 18]. The breast is considered a symbol of womanhood and sexuality, and having breast cancer or receiving surgical treatment is a traumatic experience for a woman due to its impact on self-image [14]. Previous reports in the literature state that anxiety and depressive symptoms were found during follow-

up in women who had a mastectomy. One year after mastectomy, moderate depression was seen in 39% of patients. The possible loss of femininity and attractiveness, an impaired body image, fear of recurrence, low self-esteem, and poor health are known to cause psychiatric illness [17, 18, 25]. The effect of surgical therapy on psychosocial outcome is controversial [21]. Reich et al. [14] reported that there were no statistically significant differences in body image problems after BCS compared with mastectomy. This might be due to the fact that the rate of radiotherapy after BCS is relatively higher than after mastectomy. Problems with body image are particularly common after breast surgery. Although BCS is considered to be less disfiguring, esthetic outcomes vary widely and patients with more pronounced breast asymmetry are more likely to experience poor psychosocial functioning compared with minimal breast asymmetry [21]. In previous reports, while women with BCS had fewer changes in their body image than those who had undergone a mastectomy, no differences were found in general psychosocial outcome between mastectomy and BCS [14, 16, 17, 26]. In one study, Maraste et al. [27] reported that when various age groups were analyzed, there was a significant association between previous mastectomy and morbid anxiety scores in women aged 50–59 years, whereas no discernible association was found in other age groups. However, we did not find any significant differences between surgery type and depression, although mild depression according to BDI was more significant in patients who had undergone mastectomy. The small population size may have played a role.

The variation in prevalence of depression is due to different times of evaluation, usage of different measurements to diagnose depression, and different populations studied [14]. In our study, we used DMS-III criteria to evaluate depression by using SCID, and BDI to evaluate the severity of depressive symptoms. BDI is a screening instrument found to be an accurate self-report measure in oncology [13, 22]. Beck et al. [13] recommended a score of 10 when screening for mild depression, 16 for mild to moderate depression, 20 for moderate to severe depression, and 30 for severe depression [13, 17, 22].

In conclusion; age, lactation, family history of breast cancer, having had children, marital status, and consultation with a second surgeon were important in the decision making process regarding breast cancer surgery in this Turkish population. The fear of recurrence and non-curative outcome might have outweighed cosmetic appearance in our patients so they mostly chose mastectomy. As a result of our study, we feel that mastectomy did not cause more psychosocial disturbance than BCS.
